### **Abstract**

This paper assesses the role of sales as a feature of price dynamics using scanner data. The study analyses an extensive, high frequency panel of supermarket prices consisting of over 230,000 weekly price observations on around 500 products in 15 categories of food stocked by the UK's seven largest retail chains. In all, 1,700 weekly time series are available at the barcode-specific level including branded and own-label products. The data allows the frequency, magnitude and duration of sales to be analysed in greater detail than has hitherto been possible with UK data. The main results are: (i) sales are a key feature of aggregate price variation with around 40 per cent of price variation being accounted for by sales once price differences for each Unique Product Code (UPC) level across the major retailers are accounted for; (ii) there is considerable heterogeneity in the use of sales across retailers; (iii) much of the price variation that is observed in the UK food retailing sector is accounted for by price differences between retailers; (iv) only a small proportion of price variation that is observed in UK food retailing is common across the major retailers suggesting that cost shocks originating at the manufacturing level is not one of the main sources of price variation in the UK; (v) own-label products also exhibit considerable sales behaviour though this is less important than sales for branded goods; and (vi) there is some evidence of coordination in the timing of sales across retailers insofar as the probability of a sale at the UPC level at a given retailer increases if the product is also on sale at another retailer.

**Keywords:** Sales, price variation, retail prices.

## **Sales and Retail Price Dynamics: Evidence from UK Food Retailing.**

### **1. Introduction**

In this paper, we explore the role of sales in explaining the dynamics of retail food prices using scanner data for all major retailers in the UK food sector. In general, the role of sales matters from two broad perspectives: first, set against a background that is often characterised by ‘sticky’ prices, sales play a potentially important role both in respect of temporary price variation and retail price inflation more generally (Kehoe and Midrigan, 2008); second, from an industrial organisation perspective, the issue arises with respect to understanding price setting and the extent to which firms compete via temporary reductions in price. As a consequence, the role of sales in explaining retail price movements has received some attention in the recent macroeconomic and industrial organisation literature, often with specific reference to retail food prices. Most notably, using US data, Hosken and Rieffen (2004) emphasize the importance of sales in overall price adjustment and provide evidence that sales are a significant feature of retail price dynamics. Specifically, depending on the product category, they report that 20 to 50 per cent of the annual variation in retail (food) prices is due to sales. Nakamura and Steinsson (2008) report that 20 per cent of price changes are due to sales which are typically concentrated in relatively few sectors such as food and clothing. Berck *et al.* (2008) use weekly data on orange juice in the US. They note that the existing industrial organisation literature on sales implicitly assumes that sales are determined by manufacturers not retailers while their results suggest that understanding the role of retailers is key in understanding sales behaviour<sup>1,2</sup>. The issue

---

<sup>1</sup> This issue has also been highlighted by Hosken and Rieffen (2004).

of whether sales originate at the retail level rather than being determined by manufacturers is also addressed by Nakamura and Steinsson (*op. cit.*) and Hosken and Rieffen (*op. cit.*)<sup>3</sup>.

In this paper, we contribute to the empirical literature on sales and the role of sales in price variation using high-frequency (weekly) data on UK food retailing with scanner data covering all the major food retailers in the UK. Our coverage provides the most comprehensive overview of the role of sales in retail food price dynamics to date by identifying the extent and importance of sales for over 500 food products using high frequency (weekly) data for all major retail chains in a well-defined market, the data also allowing us to separate out the existence of sales for own-label and branded products. Specifically, we use scanner data at the Unique Product Code (UPC) level, covering 500 products in 15 categories of food sold in the UK's seven largest food retail chains over a two and a half year period from September 2001 to April 2004. The data we employ are at weekly intervals rather than monthly (see, in comparison, Hosken and Rieffen (*op. cit.*) and Nakamura and Steinsson (*op. cit.*) who use monthly), which is an advantage if promotions exist for only one or two weeks at a time (Hosken and Rieffen, *op. cit.*)<sup>4</sup>. In addition, the UPC data is available at the individual retailer-level and our coverage relates to all the major food retailers in the UK, giving 1,704

---

<sup>2</sup> Most notable contributions that address the issue of sales include Varian (1980), Sobel (1984), Pesendorfer (2002) among others. These papers relate sales either to firms discriminating among different types of consumers or over time. Another strand emphasises the role of store inventories. For an example of the latter, see Aguirregabiria (1999).

<sup>3</sup> The observation that sales are more likely to be driven by retailers rather than manufacturers is also noted by Nakamura (2008), the role of retailers in price behaviour more generally being highlighted by Villas-Boas (2007) and Chevalier *et al.* (2003) among others.

<sup>4</sup> Data frequency and how the data are reported is an issue in identifying sales. In Nakamura and Steinsson (2008), the data is monthly and comes from the Bureau of Labor Statistics (BLS) used to construct the consumer price index where a 'sale' is denoted by a sale flag when the data is collected. Nakamura (2008) uses weekly scanner data at the UPC level by retailer and store for one year. Berck *et al.* (2008) use weekly scanner data for two product categories (fresh and concentrated orange juice) across stores and retailers across the US. In the latter, they have to define what will be categorised as a "sale" in the data, which is the approach that is also followed here. Determining a sale in this manner is also the approach followed by Hosken and Rieffen (2004).

UPCs in all. The UK's food retailing sector is highly concentrated and with the retail chains reportedly employing national pricing strategies, the data coverage here offers important insights into the significance of sales across different retail chains.<sup>5</sup> Finally, the UPC data we use separates out own-label products from branded products for each of the major retailers, so we are able to offer an assessment based on brand status, something that was not possible in the studies by Hosken and Rieffen (*op. cit.*) and Nakamura (*op. cit.*). This distinction has been highlighted by Berck *et al.* (*op. cit.*) but the data coverage in their paper related to orange juice products only. As such, we offer a more general perspective on the brand/own-label distinction relating to the contribution of sales in retail price dynamics.

Our key results are as follows: (i) sales are a key feature of aggregate price variation with around 40 per cent of price variation being accounted for by sales once price differences for each UPC level across the major retailers are accounted for; (ii) much of the price variation that is observed in the UK food retailing sector is actually accounted for by persistent price differences between retailers; (iii) there is considerable heterogeneity in the use of sales across retailers; (iv) only a small proportion of price variation that is observed in UK food retailing is common across the major retailers, suggesting that cost shocks originating at the manufacturing level is not one of the main sources of price variation in the UK (this observation being consistent with Nakamura (*op. cit.*) and Hosken and Rieffen (*op. cit.*) for the US but with the evidence reported here being suggesting that the role of 'common' shocks to be less important than in the US); (v) own-label products also exhibit considerable

---

<sup>5</sup> Concerns about the potential for market power exerted by UK food retailers have attracted the attention of the UK Competition Commission. See Competition Commission (2000) for a comprehensive overview of this sector and assessment relating to concerns about market power. In 2005, the four leading retailers had a combined share of around 75 per cent of the retail grocery market (Office of Fair Trading, 2006).

sales behaviour though this is less important than sales for branded goods; and (vi) there is some evidence of coordination in the timing of sales across retailers insofar as the probability of a sale at the UPC level at a given retailer increases if the product is also on sale at another retailer.

The paper is organised as follows. In Section 2, we describe the data that forms the basis for the analysis of sales. In Section 3, we present a discussion of the methodological issues in identifying sales periods and, in Section 4, we provide a summary of the principal features of sales in the UK food retailing sector. In Section 5, we provide an overall assessment of the relative importance of sales in price variation and gauge the role of sales against ‘common’ price changes originating from the manufacturing sector and retailer-specific price variation. We address the timing of sales across retailers in Section 6 and, in Section 7, we summarise and conclude.

## **2. Price Data**

In the empirical analysis, we utilise an extensive and high-frequency panel of supermarket food prices derived from electronic point of sale (EPOS) data obtained from *Nielsen Scantrack*, a leading market research company which collects data relating to in-store transactions. Our data derives from the records of the seven largest of these supermarkets which, as a group, represented around three-quarters of all food sales in the UK during the sample period.<sup>6</sup>

---

<sup>6</sup> The seven supermarkets included in the sample are Tesco, Sainsbury, ASDA, Safeway, Somerfield, Kwik Save and Waitrose. The remaining 25% of sales are accounted for by small national and regional supermarket chains and independent retailers. Discounters such as Lidl, Netto and Aldi did not submit data to Nielsen at the time of the sample, but together accounted for less than 3% of market share. Marks and Spencer did not sell branded goods and are excluded for this reason.

The price information contained in the data set is based on the details recorded by laser bar-code scanners as products pass through supermarket check-outs. As a result, prices are based on 100% of transactions of the sampled products rather than derived from consumer surveys. Overall, the data covers 231,069 weekly price observations on 507 products in 15 categories of food.<sup>7</sup> They relate to a (137 observation) sample frame running from 8<sup>th</sup> September 2001 to 17<sup>th</sup> April 2004. Some 90% of products are available throughout this period, the minimum number of observations for any product being 103 weeks.<sup>8</sup>

Each price observation in the sample represents the simple average of the prices posted in each of the retailers' stores on the Saturday of each week. Price observations are thus retailer-based national (Great Britain) averages. For a retailer such as Tesco, the largest in the UK, prices are averaged over those posted in several hundred of its stores nationwide. While store managers may have some flexibility over pricing, particularly for perishable items, the large number of products stocked in most stores (which typically exceeds 25,000) mitigates against widespread differences between stores. Also, major UK grocery retail chains claim that national pricing strategies are the norm for the bar-coded food products (Competition Commission, 2000).

One key feature of the prices is that they incorporate the effect of promotional activity. The price data used in this study include all promotional activity, whether in the form of price (e.g. '50% off') or quantity ('buy-one-get-one-free') discounts. Discounts

---

<sup>7</sup> The 15 categories are orange juice, instant coffee, breakfast cereals, teabags, yoghurt, wrapped bread, tinned tuna, tinned tomatoes, tinned soup, corned beef, fish fingers, frozen peas, frozen chips, Jam and frozen pizza.

<sup>8</sup> Time series are contiguous (in that there are no missing observations once the time series has begun) in 100% of cases, although some (10%) start later than 8<sup>th</sup> September. All time series finish in the week ending 17<sup>th</sup> April 2004.

relating to store ‘loyalty’ cards are not included since they apply to the consumer’s total spend rather than the prices of specific products.

The data set identifies products at a highly detailed level. In general, two products are distinct if they have different bar-codes, so that 100 gram and 200 gram jars of the same brand of instant coffee are different products for which separate prices are recorded. Furthermore, many of the products are national brands that are sold by all retail chains, so the data set contains retailer-specific prices of such products. We identify each retailer-product combination with a Unique Product Code (UPC), so that, for example, a 100 gram jar of Nescafe ‘Gold Blend’ instant coffee stocked by Tesco and Sainsbury are two separate UPCs each with their own time series of weekly prices. In all there are 1,704 such UPC price series, the distribution of which is summarised in Table 1.<sup>9</sup> Data (percentage of data set) are most prevalent in the bread (34%), soup (18%), coffee (8%) and orange juice (6%) categories, each of which contain in excess 100 UPCs. The least populated categories, such as frozen fish fingers (1%) and frozen pizza (1%), contain 20 UPCs each. As is evident from these figures, the data set does not fully reflect consumer spending on food (fresh fruit and vegetables are not part of the dataset since they do not carry unique bar-code indicators) but the range of categories is nevertheless broad, spanning beverages and foods across a range of formats (fresh, chilled ambient and frozen).

---

<sup>9</sup> Each price observation is uniquely identified by its UPC and the (week ending) date but because the data set is an unbalanced panel (in that not all products are sold in all supermarket chains in all weeks) summary statistics vary slightly depending on the standardisation that is used. For example, orange juice accounts for 5.33% of the product codes, 6.34% of the UPCs (product code  $\times$  retailers stocking the product) and 6.40% of the observations (product code  $\times$  retailers  $\times$  weeks). Unless specifically stated, UPC (i.e. the product code-retailer combination) will be taken to represent the principal unit of analysis when describing the dataset.

As Table 1 also shows, seven categories contain products in both branded (sold with the manufacturer's name) and own-label (sold under the retailer's name) forms. Own-label products with the same product profile (e.g. an 800 gram standard medium sliced white loaf) are treated as one product and have the same product code in the data base. Retailer-specific prices of these products (i.e. UPCs) represent the Tesco own-label 800 gram standard medium sliced white loaf or the Sainsbury own label 800 gram standard medium sliced white loaf, for example. Hence, own-label versions of the same product are treated analogously to the branded products stocked by multiple retailers in the *Nielsen Scantrack* data set. In the UK, where sales of own-label products account for a significant minority of the total consumer spend, this dimension of the data set offers potential insights in to any differences between the pricing of manufacturer- and retailer- branded products. Own-label products account for nearly one-fifth of the products listed in the data set.

### **Table 1 Here**

One of the most interesting aspects of the data set is that prices are available by retail chain, facilitating comparison of price and sales behaviour for identically bar-coded products across retailers. The 1,704 UPCs belong to 507 bar-coded products and Table 2 details at a dis-aggregate level how these products are distributed across retailers, broken down by label.<sup>10</sup> As is clear, not every product is stocked by all retailers but two-thirds (64%=325/507) are sold in at least 2 retailers, and 18% sold in all seven. In terms of the distribution of products by label, some 71% (=267/375) of branded products are sold in at least 2 retailers with 21% sold in all seven. For own-label

---

<sup>10</sup> Note that the entries in Table 2 refer to products (e.g. 100g jar of Nescafe 'Gold Blend' instant coffee) rather than UPCs (100g jar of Nescafe 'Gold Blend' instant coffee in Tesco) and thus proportions in the table need not correspond to those in Table 1. See previous footnote for clarification.

products, comparable statistics are 43% and 11% suggesting that coverage is reasonably broad across the market as a whole, particularly for branded goods.

**Table 2 Here**

Finally, Table 3 shows how the UPCs are distributed by retailer. The figures suggest that all seven supermarkets are well-represented in the sample, Tesco having the largest number of observations at 17% and Waitrose the fewest at 11%.

**Table 3 Here**

To give a flavour of the data, Figure 1 presents the prices of eight well-known branded products selected from the data set on the basis that they are sold in most if not all of the retail chains. Hence, for each product, there are seven UPCs representing the national average prices in each of the retailers at weekly intervals. Although accounting for a small fraction of the prices in the data set, they display a number of interesting features, in particular is the way that sales punctuate the time series, albeit with a frequency and intensity that varies by product and retailer. When not on sale, prices tend to coalesce around particular levels, although this ‘regular’ (i.e. non-sale) price changes at discrete points in the sample. It is also apparent that, despite representing the prices of identically bar-coded products, there are persistent and substantial differences in the prices charged by retail chains.

**Figure 1 Here**

Using the entire data set, the average difference between the highest and lowest weekly prices paid for products with the same barcode is 30%. For branded products this dispersion is 27% and, for own-label products, 45%. While these figures underline the fact that price dispersion is pervasive and significant, it seems likely that such dispersion arises from not only from persistent price differentials across retailers but also the compounding effect of sales.

Before we attempt to disentangle the contribution of these effects to overall price variation, it is useful to investigate the dispersion of average prices charged by each retailer over the sample. To do so, consider Table 4 which details the average prices of products in each retailer for branded, own-label and all products (i.e. branded and own-label combined). As alluded to above, not every product is stocked by all retailers so the table reports prices based on two classifications of products: (a) those products stocked in each retailer and (b) the subset of 92 products (comprising 78 branded 14 own-label) and that are stocked by all seven retailers. Being common to all the retailers, these products typically represent market leaders, major national brands and everyday own-label products such as standard white loaf and tinned tomatoes. The table also lists the rank order of average prices by supermarket (1 denoting the cheapest) and the number of price observations upon which the averages are based.

With differences according to the product grouping and label status, the picture is a complex one, but a few features are particularly noteworthy. In terms of the classification given by (a) namely, the products that each supermarket stocks, there appears to be a cluster of supermarkets (Asda, Somerfield and Kwik Save) selling

branded products at low cost and another cluster of mainstream retailers (comprising Asda, Tesco and Sainsbury) selling own-label products at low cost.

While offering a useful summary of pricing across retailers, it is price comparisons based on a common basket of products that should generate a more accurate comparison. Using the prices of the 92 products stocked in all seven retailers, we find that a single cluster of supermarkets (Asda, Tesco, Sainsbury and Kwik Save) offers low prices in both branded and own-label product categories. One retailer (Asda) appears in all such clusters and leads the rankings whichever way the data are classified. While it offers the same average price for the set of branded products as the UK's largest retailer, Tesco, its prices of like-for-like own-label products are markedly lower than its rivals.

Overall, the following stylised facts emerge from this simple analysis of average prices, namely: (i) the average prices for national brands and brand leaders are remarkably similar, particularly among the four retailers with the lowest average prices; (ii) there is a significant premium for branded products; (iii) when comparing the like-for-like products in our sample, it is the mainstream retailers that offer the lowest prices for both branded and own-label products. Clearly, when assessing the role of sales in retail price variation, we need to control for the underlying intra-retailer price differences at the UPC level.

**Table 4 Here**

### 3. Creating Sales Data

In order to investigate the impact of sales, an indicator variable is created to identify sale periods. Prices are generally not declared as ‘sale’ or ‘regular’ by manufacturers or retailers in the data sets constructed by government departments or commercial organisations, with the result that the identification of sale periods is based upon the prices themselves. Broadly speaking, sales are simply periods of temporary price reduction, although the precise definition employed in empirical work varies. For example, prices supplied by the Bureau of Labour Statistics (BLS) for the construction of the U.S. Consumer Price Index is identified as ‘on sale’ if the product is sold below its ‘regular selling price’, as assessed by the Bureau’s field agents in the monthly survey. Nakamura and Steinsson (*op. cit.*) use this sales flag to identify sale periods. Hosken and Reiffen (*op. cit.*) also use BLS data but define a sale with reference to the actual behaviour of prices, rather than the field agents’ assessment. Specifically, if a price falls by more than some fixed percentage (they consider 10% and 20%) between two adjacent months ( $m-1$  and  $m$ ) but is then reversed in the following month (i.e. between  $m$  and  $m+1$ ), the product is treated as being on sale in month  $m$ . In other words, a product is recorded as being ‘on sale’ in month  $m$  if the prices in months  $m-1$  and  $m+1$  are markedly (i.e. 10% or 20%) higher. Unlike the Nakamura and Steinsson (*op. cit.*) measure, this definition implicitly restricts sales to last one month, although this is probably not an unreasonable assumption in the majority of cases. Nevertheless, because price setting typically occurs on a weekly basis, some of the finer detail of price adjustment is inevitably obscured by the use of monthly data.

In recent studies analysing weekly price data, definitions of sale prices are modified to reflect the data set’s higher frequency. For example, Campbell and Eden (2005) define

a sale to have occurred if a price decline of 10% or more between weeks  $w-1$  and  $w$  is then completely reversed within two weeks (i.e. in  $w+1$  or  $w+2$ ). Using this definition, a sale lasts for a minimum of one and a maximum of three weeks. Berck *et al.* (*op.cit.*) consider price falls of 25%, 35% and 50%, but use the store's modal price ( $\tilde{p}$ ) over a two year period as the basis for comparison rather than the price in the week preceding the decline. Using this definition, sales are recorded for all weeks  $w$  in which the price falls a certain percentage below  $\tilde{p}$ . While this approach leaves the length of sales unconstrained, it relies upon the mode being representative of the non-sale (or 'regular') price. Where regular prices changes over time (reflecting general inflation or specific changes in production costs, for example), the use of the mode to identify sales is arguably less than ideal (see below).<sup>11</sup>

The foregoing discussion serves to highlight some of the practical difficulties in identifying sales ('periods of temporary low prices') from price data alone, namely the duration of 'temporary', the magnitude of 'low' and the reference price used in the assessment of each. Mindful of these considerations, we define a sale as a period during which price falls by at least  $x\%$  of the observation immediately preceding the decline in prices, and then which is reversed within 12 weeks. With this definition, there are several points to note. First, sales of long duration (i.e. less than 3 months) are allowed for. While sales of 2-4 weeks are typically believed to be the norm and sales of longer than 6 weeks rare in UK food retailing (Competition Commission, 2000 p.116), this measure does allow for the (albeit infrequently observed) longer sale durations. Second, it is the cumulative price drop (i.e. the peak-to-trough difference)

---

<sup>11</sup> It is noteworthy that in their study of refrigerated and frozen orange juice, Berck *et al.* (2008) find evidence of a clear mode in fewer than half the refrigerated products and in two-thirds of frozen products they analyse.

that is used rather than any week-on-week change in price that is used to define the magnitude of price change. This allows for price changes that are staggered over more than a single week at the start or end of a sale period. This may be important in our data if a national price promotion is implemented over adjacent weeks. Third, it is actual prices that act as the reference price. This is likely to be useful in cases where there is no single non-sale price that applies over the entire sample. Hence, the *regular price*, refers to a state of nature (paralleling the status of the term *sale price*) rather than a fixed value such as the mode. Fourth, in recognition of the fact that results inevitably depend on the price decline that is chosen, we consider three thresholds, namely  $x = 10\%$ ,  $25\%$ , and  $35\%$ . Fifth, the sale period ends when prices return to a new regular price. With this condition, prices do not need to return to their pre-sale level. Finally, all prices between the initial decline and the subsequent reversal are counted as sale prices.

In order to illustrate the effect of these conditions in the creation of a sale indicator, consider the stylised weekly time series of prices depicted in Figure 2. While the figure is by no means representative of the price series in the data set, it exhibits some of the more problematic features that characterise some series, most notably changes in the regular price and staggered sale prices. At the top of the figure are labels (R and S denoting regular and sales prices respectively) generated by application of our sales algorithm with a 10% threshold to the stylised data. Numbers adjacent to the price levels denote the (non-zero) week-on-week percentage price changes.

In the figure, there are three episodes of lower prices, commencing at weeks  $t_\alpha$ ,  $t_\beta$  and  $t_\chi$ , although only one (at time  $t_\beta$  and shaded grey)) is recorded as a ‘sale’ by our

definition. This owes to the fact this is the only one of the three periods which satisfies the conditions that (a) the peak-to-trough price drop exceeds 10% and (b) the price returns to a level similar to the pre-sale level within 12 weeks. Note that neither of the (9%) falls that make up the 18% cumulative decline would trigger a sale using a 10% week-on-week criterion. The two other periods of price decline shown (at  $t_\alpha$  and  $t_\chi$ ) do not qualify as sales by our definition because in the first case the price decline (of 2%) is too small; and in the second case, the decline is not reversed. The ability to discriminate between sale episodes and periods in which the regular price falls is useful since both aspects of behaviour are apparent in some of the price series over the sample period. The hypothetical data also illustrate the limitations of using the sample mode (denoted by  $\tilde{p}$  in Figure 2) as a measure of the regular price or indeed monthly (rather than weekly) prices, to detect sales. Whereas changes (or trends) in the regular price undermine the former, aggregation confounds the latter; neither identifies the sale in Figure 2.

### **Figure 2 Here**

While the flexibility of the sales definition we have adopted in this paper seeks to overcome some of the key issues in data of this sort, it should not be overlooked that any set of criteria designed to distinguish sales from changes in the regular price using prices alone are to some extent arbitrary. As a guiding principle, it seems reasonable that the larger the transitory price decline is, the more likely it is that the observations represent a sale. For this reason, we initially consider (peak-to-trough) price drops of 10%, 25% and 35% in sales identification, a description of which is presented in the following section.

#### 4. Sales Data

Table 5 reports summary statistics of the sales defined according to 10, 25 and 35 per cent thresholds. It shows that nearly 8% of prices are classed as ‘on sale’ using the 10% threshold, a figure that drops to 3.5% and 1.4% using the larger discounts. Thus while sales are clearly the exception to the normal rule of pricing, only very deep sales are rare. Table 5 also reports the proportion of time series that contain at least one sale episode and here the incidence of sales is more evenly distributed. Specifically, two-thirds of all time series have been on a 10% sale, one-fifth experiencing a deep (35%) sale. Taken together, the statistics suggest that sales are unusual but commonly applied across products. Interestingly though, around one-third of the series are never discounted (using the 10% measure) during the three years they are observed.. The figures in Table 5 also suggest that sales tend to be around four weeks long irrespective of their depth, a degree of consistency that suggests that the sales definition is indeed able to discriminate between sales and changes in the regular price.<sup>12</sup>

#### Table 5 Here

In terms of the number of sale episodes (rather than the number of observations), the dataset contains 4,309 10% sales, of which around half (2,024) are sales of greater than 25% and one-fifth being sales of greater than 35%. These figures imply that on average a UPC will experience a 10% sale around 2.5 times during the sample (a little under once per year), a figure that rises to four (just over 1.5 per year) if we consider only those UPC that have ever been discounted. These averages mask notable

---

<sup>12</sup> Had the duration of 10% sales differed substantially from that using other sales depths, it may have suggested that a significant proportion of 10% sales were merely changes in the regular price.

differences between branded and own-label products. While the duration of sales is similar, branded products tend to be discounted both more frequently and more deeply than own-label products. As is clear from the distribution of sale episodes per UPC displayed in Figure 2, most products that have been on sale, have only ever been discounted once during the sample frame, although there are a small number of frequently discounted products.

For a more complete picture the distribution of sales depth, consider Figure 3. While sales in excess of 80% have occurred in a handful of cases, discounts in excess of 50% are rare, accounting for less than 5% of all sales. The majority of sales represent discounts of between 10 and 30%, the median discount being 24%.

**Figure 3 Here**

**Figure 4 Here**

Finally, to gain an impression of the use of sales by each of the national retailers, consider Figure 5 which shows the proportion of each retailer's prices that are sales under the three thresholds. There are quite marked differences across retailers: Asda uses sales rarely (almost one-tenth of the average); Safeway, Somerfield and Kwik Save form a group of 'discounters' in that the use of sales is above average for the food retailing sector as a whole; Tesco, Sainsbury and Waitrose are "average" users of sales activity. This classification is consistent across the depth of sales but becomes increasingly apparent the deeper the sale. All use deep sales rarely, this being even less

common for Tesco, Sainsbury Waitrose and Asda. Reflecting the comparison of average prices as detailed in section 2, the data suggests considerable heterogeneity among retailers on the use of sales.

### **Figure 5 Here**

The statistical description of sales presented above suggests a number of stylised facts, which are summarised as follows: (i) sales are unusual, occurring less than 10% of the time; (ii) marketing strategies differ markedly, even among mainstream retailers; (iii) most UPCs experience a sale, although around one-third do not; (iv) brands are discounted twice as frequently as own-labels; (v) a small number of products are discounted frequently; (vi) sales last around four weeks; (vii) sales typically represent discount of 25%.

## **5. The Importance of Costs and Sales in Price Variation**

In this section, we explore the role of ('common') cost changes and sales in the overall variation of retail prices. To address these issues, we also have to account for the differences in average prices at the UPC level across retailers as detailed in Section 2. Clearly, if cost changes account for a significant proportion of retail price variation once the intra-retailer differences are accounted for, this would be consistent with the manufacturing sector (or other upstream stage) being the main source of retail price variation. However, if sales account for a large proportion of retail price variation, then this could reflect the role of retailers as determining price variation particularly if sales

feature significantly for the prices of branded and own-label products and given that sales activity appears to be fairly heterogeneous across retailers.<sup>13</sup>

Specifically, we use simple regression models to gauge the relative importance of these in price variation. To do so, we estimate price regressions containing increasingly rich sets of dummy variables: in Model 1, the baseline specification, we fit a set of UPC-based dummy variables to the price data (i.e. one dummy for each UPC), around which variation can be assessed. In this model, the coefficient attached to each UPC dummy represents the average weekly price of a bar-coded product (such as a 200g jar of Nescafe standard blend instant coffee) at each retailer stocking the product over the sample period. In Model 2, the UPC-based dummies are augmented with a set of product-level variables that represent the market (i.e. across all supermarkets) average regular price for each product (such as a 200g jar of Nescafe standard blend instant coffee) in which all sale prices have been replaced by the last regular price preceding each sale. Purged of promotional prices, this variable offers a means by which we can capture underlying movements in the regular prices, of which changes in production costs (such as the price of coffee beans) are likely to matter.<sup>14</sup> In Model 3, a set of sales dummies is also included, each dummy representing a unique sale episode. With prices in all models being expressed in natural logarithms, the regression standard errors represent the standard deviation of UPC prices as a proportion of the mean level during the sample, and it is this that we use to evaluate the impact of ‘costs’ and sales in UPC level price variation. These results suggest that retail food prices in the UK are fairly sticky, that ‘common’ cost changes are not a principal cause of retail price

---

<sup>13</sup> Of course, the variation of sales activity across retailers could reflect price discrimination by manufacturers given the heterogeneity of sales behaviour across retailers. However, the presumption would be that retailers (not manufacturers) would be able to determine the (sale) prices of own-label products.

<sup>14</sup> Nakamura (2008) and Hosken and Rieffen (2004) offer similar tests on US data.

variation and that, in the context of relatively sticky prices, sales activity account for a significant proportion of the retail price variation that is observed.

To facilitate comparison across the models, we use price data from the 967 UPCs that are sold in at least two supermarkets and have experienced a sale of at least 10% during the sample period. The parameters of Models 1, 2 and 3 are estimated by ordinary least squares using 132,280 price observations and the regression standard errors (rse) reported in Table 6. Results for the ‘All’ regressions head the table with results by label and retailer appended beneath. The results suggest that the standard deviation of prices at the UPC level is around 12%, a figure that changes little we confine the analysis to brands or own-label. Allowing for our cost proxy- the movement in the industry average regular prices- (Model 2) reduces the standard deviation by a little over one percentage point, a result that holds irrespective of the brand/own-label distinction. Accounting for sales (Model 3) has a more marked effect, reducing the variation by over four percentage points but here the effect of sales is larger for brands (4.6%) than own label products (3.1%).

These results are comparable with those of Hosken and Rieffen (*op.cit.*) and Nakamura (*op.cit.*). They also conclude that sales account for a high proportion of price variability though the extent of price stickiness is lower for the data used here than Nakamura (*op.cit.*) finds for the US. In her study, she reports that only 16 per cent of price variation is common across all stores selling an identical product. The reduction in the rse as we move from Model 1 to Model 2 suggests that around 9 per cent of price variation is common across the UK food retailing sector.

Turning to price variation by retailer, Table 6 suggest a group of retailers headed by Safeway (at 15%) with relatively high price variation, and a group of retailers lead by Asda (at 9%) with the lowest variation. Interestingly, while Asda uses sales infrequently (see Figure 5), its' price variation is only marginally lower than other mainstream retailers, suggesting that Asda has a tendency to change regular prices more than other similar retailers. The effect of our costs measure is broadly the same across retailers with the result that patterns in overall price variation are driven by promotional behaviour.

Comparison of the variation between the models in Table 6, delivers estimates of the contribution of costs and sales in UPC price variation. Using the 'All Products' classification, costs account for 11% of the price variation, a figure which changes little by label. Of primary interest is the contribution of sales, which turns out to be 37% overall, with a marked difference between brands and own-label products (39% and 26% respectively). The corresponding proportions by retailer are shown in Figure 6, where the patterns in the absolute levels of price variation are reflected in the relative measures, namely that, while industry costs have broadly relatively small and broadly similar effects across retailers, the contribution of sales is around 40% of UPC price variation in all with the exception of Asda.

### **Table 6 Here**

Taken together, the picture that emerges from this analysis is one in which sales dominate the effect of costs (as proxied by industry average regular prices, at least) in price variation and combined they account for nearly two-thirds of price variation at

the UPC level. Furthermore, sales are more important for branded products so that by these measures, idiosyncratic shocks are relatively more important for own-label products than brands, possibly reflecting their less uniform composition within the product definition. While the market segments by sales behaviour to some extent, it is also remarkable how important sales are for all retailers.<sup>15</sup>

### **Figure 6 Here**

#### **6. Are Sales Across Retailers Related?**

Since we have prices by retailer, we can address whether sales behaviour is related across retailers. Recall, first of all, that the use of sales by retailer varies (see Figure 6). Taking sales greater than 25% as the benchmark, three retailers are higher employ sales than average, Tesco (the market leader) is a below average user of sales, while Asda hardly ever employed sales over the sample period. Taken from a general perspective, the raw data therefore indicates that sales are unlikely to be a common experience across retailers. However, to address the issue more directly, we assess whether the probability of a sale in one retailer is influenced by a sale in another retailer using the data available at the UPC level. The central idea here is to determine whether a sale in a specific UPC introduced by a given retailer is a random event or may be related to the presence of a sale in one or more rival retailers.

---

<sup>15</sup> As a final step, we carried out the same analysis by UPC. As Hosken and Riefen (2004) note, the relative role of costs and sales can vary across products. The results do not differ significantly from the above: prices are relatively sticky across for UPCs that constitute a product group and the role of costs is fairly marginal in each case. Sales account for a higher than average proportion of price variation some frozen UPCs (e.g. peas, pizzas) and a lower than average proportion of price variation for bread. Since the results do not provide additional insights beyond those made above, we do not report them in the text. Detailed results are available upon request.

To address this issue, we employ a fixed effects conditional logit model. Specifically, let  $s_{ijt}$  be a binary categorical (dummy) variable with 1 denoting a sale price and zero for a non-sale price for product  $i = 1, \dots, I$ , retailer  $j = 1, \dots, J$  at time  $t = 1, \dots, T$ . In order to evaluate whether sales of like products in rival retailers affects the probability that the product will be on sale (i.e. discounted) elsewhere, we create a  $K \times 1$  vector of dummy variables,  $\mathbf{r}_{it}$ , [ $\mathbf{r}_{it} = r1_{it}, r2_{it}, \dots, rK_{it}$ ] that indicates whether product  $i$  is on sale in a rival retailer  $k$ . Because each of the variables in  $\mathbf{r}_{it}$  refers to each retailer as a rival, they are matched with the retailers in  $s_{ijt}$  such that  $rk_{it} = 0$  for  $k = j$  (as  $j$  cannot be a rival for itself)<sup>16</sup>. Note also that  $rk_{it} = 0$  when the product is either not stocked by retailer  $k$  or stocked but not on sale. Observations where  $rk_{it}$  equals unity signal that product  $i$  is stocked in retailer  $j$  and  $k$  and on sale in retailer  $j$  ( $k \neq j$ ). For example, when considering sales in supermarket 1, i.e.  $s_{i1t}$ ,  $r1_{it}$  is zero since those observations refer to itself and thus not a rival. Hence  $r1_{it}$  equals one when considering a product  $i$  in at time  $t$  that is on sale in supermarket 1 and stocked by retailer  $k = 2, \dots, J$ . Finally, let  $M_{ikt}$  be a dummy variable indicating whether product  $i$  is on sale in period  $t$  in at least one other retailer in the market, zero otherwise. In other words, we have an indicator variable:

$$M_{ijt} = 1 \text{ if } \sum_{k=1}^J rk_{it} > 0 \text{ for } j \neq k$$

$$M_{ijt} = 0 \text{ otherwise}$$

---

<sup>16</sup> The focus on a “like” product here refers to the identical UPC that is sold across one or more other retailers (e.g. a 200g jar of Nescafe). This raises the issue of closely related products. For example, whether the sale of a 200g jar of Nescafe is related to a 350g jar of Nescafe or a 200g jar of Nescafe is related to the sale of a 200g jar of another brand of coffee. One difficulty in posing the issue in this way is that the bounds of defining the product space become unlimited. Therefore, to keep the issue manageable, we stick with the sale at the identical UPC level across retailers.

If product  $i$  is only stocked by one supermarket, the set of  $J$  dummy variables  $rk_{it}$  will each be zero and hence  $M_{ijt}$  will be zero. Where this happens (about one-third of the products are only sold in one supermarket), product  $i$  drops out of the regression analysis. To investigate whether sales are affected by presence of a sale elsewhere in the market, we estimate:

$$s_{ijt} = \alpha_i + \beta M_{ijt} + \varepsilon_{ijt} \quad (1)$$

where the  $\alpha_i$  represent the UPC-based heterogeneity (fixed effects) and  $\varepsilon_{ijt}$  are disturbances with constant mean and variance. Assuming that  $\varepsilon_{ijt}$  are uncorrelated with the timing of sales in supermarkets, i.e.  $E[\varepsilon_{ijt} | M_{ijt}] = 0$  then, given that  $s_{ijt}$  is a binary variable,  $E[s_{ijt} | M_{ijt}] = P[s_{ijt} = 1 | M_{ijt}]$  implies that  $\beta$  is the predicted partial marginal probability of a sale on a product given a sale of the same product in at least one other supermarket at time period  $t$ . Clearly, if a sale of a product at one retailer is independent of the identical product being on sale at any other retailer,  $\beta = 0$ . Where  $\beta > 0$  ( $\beta < 0$ ), this indicates that a sale in a given retailer for a specific UPC is more (less) likely given the existence of a sale elsewhere in period  $t$ .

We further amend the test by identifying separately whether the sale of the product is related across retailers for own-label products. In this case, the own-label definition relates to the “same” own-label product sold across retailers. For example, we are relating the sale of Tesco 1 litre orange juice with Sainsbury’s 1 litre orange juice. *A priori*, we may expect less relatedness in the sale of products across retailers when it applies to own-label goods.

Table 7 reports the estimated probability that a product will be on sale given that it is on sale in at least one other retailer using the marginal effects of the conditional logit model. The results, which are reported for both branded and own-label products, reject the hypothesis that a sale by a retailer is unrelated to the existence of a sale in the same UPC elsewhere for branded products but not in the case of own-labels. Specifically, (10%) sales in branded products increase the likelihood of sales in rivals stocking the product by some 14.3%, a probability that rises slightly for deeper sales. Thus, sales on branded products are not random events, but are to some extent co-ordinated, suggesting a tendency for promotions to be uniformly offered across (at least a subset of) retailers. However, the probability is not ‘high’ in the sense that the results do not indicate that there is perfect coordination in the use of sales. Own-label products present a contrasting picture: namely, for 10% and 25% sales, the results indicate that sales are independent across retailers though, for the 35% sale category, sales are not independent. Given that sales with the 35% benchmark are considerably less common, we can conclude that in most cases, sales of own-label goods by retailers are independent.<sup>17</sup>

### **Table 7 Here**

## **7. Conclusions**

This paper presents an analysis of promotional sales using an extensive, high frequency micro-economic database of supermarket prices in the UK. Given that the timing of

---

<sup>17</sup> We also investigated whether sales behaviour by retailer related to the intensity of sales behaviour across other retailers. Specifically, the discussion in the text relates to whether the sale by one retailer related to the product being on sale at any one of the other retailer. We further investigated the issue in terms of whether the probability of a sale by one retailer depended on how many other retailers the product was on sale at. The results indicate that the probability of a sale increases depending on the number of retailer which also had the product on sale. For example, for the greater than 25% sale benchmark, the probability that the product was on sale at one other retailer was 16.2%; if the product was on sale at two or more retailer, the probability increased to 24.7% with estimates statistically significant at the 5% level. Results are available on request.

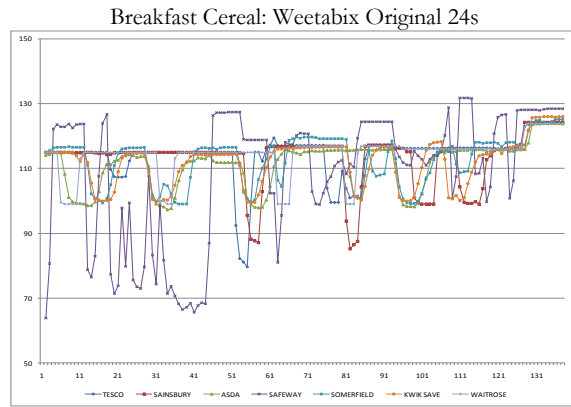

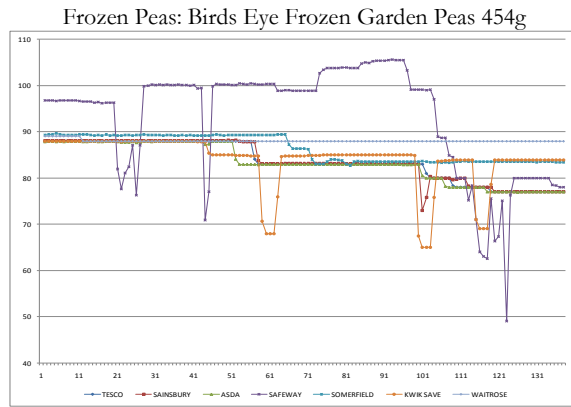

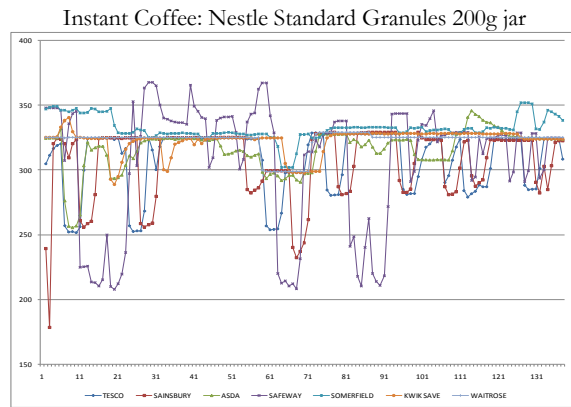

sales is not recorded, it must be inferred from the prices themselves and the method that we have adopted for the identification of sales is described (and is consistent with other recent research on sales). Using a 10% peak-to-trough measure, we find that 92% of prices are regular, the remainder represent sales. So, although sales are unusual, the majority of products experience a sale, the norm being around one sale per year. While there are marked differences in the number of times products are on sale (one-third of the 1,700 UPCs considered were never on sale in the sample period), promotional activity generally lasts 4 weeks and represents discounts that average 25%.

The paper also offers an assessment of the importance of sales in overall price variability. In general, retail prices are relatively sticky with 'common' cost changes originating from the manufacturing sector accounting for only a small proportion of overall price variability. This general result is consistent with results using data from the US though the evidence presented here suggests that common cost changes account for a smaller proportion of overall price variability than reported in the US studies. Against this background of relative price stickiness, sales are relatively important accounting for around 40 per cent of overall price variability over the data period. However, prices and sales activity vary considerably across the major UK food retailers and this dispersion is a particularly notable dimension of the data. Further results indicate the retailer sales' activity is not independent and that own-label products are also as likely to be on sale as branded products. Taking together, the results suggest two broad conclusions that relate to both the macroeconomic and industrial organisation literature: first, sales are an important feature of price dynamics; second, the role played by retailers is key to understanding price variation.
