ABSTRACT

So far, various graphite-Nickel Oxide (NiO) composites have been investigated as anodes for Li-ion batteries. However, developing an ideal composite that overcomes NiO's electrical conductivity limitations remains a significant challenge. The current study presents an in-situ one-step hydrothermal technique for integrating NiO into a 3D peony-like graphitic nanostructure (NiO-GNF), resulting in unique thin nanosheet arrays with porous, conductive channels. Notably, the composites endowed controlled aggregation and restacking of NiO, buffered electrode stress and improved electrical conductivity due to the expanded nature of graphite. In addition, the enlarged interlayer spacing of expanded graphite facilitated an improved Li-ion insertion. Overall, in comparison to pure NiO anodes, the NiO-GNF composite achieved an impressive electrochemical improvement exhibiting a highly reversible discharge capacity of 678.2 mAh/g after 370 cycles at a current density of 0.5 A g^{-1}, corresponding to a capacity retention of 60.7 %. The composite also demonstrated a capacity of 752 mAh/g at a high current density of 1.2 A g^{-1}.

INTRODUCTION

Lithium-ion batteries (LIBs) are considered as one of the most promising power sources for mobile, portable electronics, and electric vehicles (EVs) due to their excellent energy efficiency, high cell potential, low cost, and long cycle life. However, the commercial graphite used in LIBs is insufficient to meet the current market demands owing to a limited theoretical capacity of $\sim$ 372 mAh g^{-1}.[1] As potential high energy substitutes; transition metal oxides (TMOs), such as Co, Ni, Fe, Cu, Ti, and Zn oxides and their composites, have garnered research attention due to their exceptional storage capacity and high energy density of approximately 700 mAh g^{-1}, according to the equation of $MO + 2Li^+ + 2e = M + Li_2O$.[2-8] Amongst metal oxides, nickel oxide (NiO) is highly appealing as a promising anode for LIBs due to their abundance, low cost, eco-benignity, admirable safety, and high volumetric energy density.[9] However, pristine NiO utilization, as for other oxides, significantly failed as an effective anode for LIBs due to their poor electrical conductivity, low rate performance, and limited cyclability.[10]

One effective protocol used in the literature is combining NiO with carbon nanostructures. A carbon-based composite design not only provides more surface area but also offers increased electrical conductivity and desirable mechanical flexibility that buffers the volume expansion of NiO. Various carbonaceous matrices have been extensively studied, including graphite, graphene, hard carbon, carbon nanofibres, and carbon nanotubes.[10-21] For instance, Li *et al.* have revealed that the capacity and capacity retention of pristine NiO can be significantly enhanced by incorporating them into the graphene matrix. This approach leads to the formation of flower-like nickel oxide/reduced graphene oxide (NiO/RGO) nanocomposite, which can exhibit a specific storage capacity of 702.3 mAh/g and capacity retention of 77.0 % after 100 cycles at a current density of 0.1 A g^{-1}. Similarly, Shi *et al.*

69 developed a 3D graphene/NiO nanobelt composite, which significantly enhanced graphene's

70 volumetric and specific capacities by 75 and 41%, respectively. The composite formed

71 displayed a cycling life of 360 cycles, and a specific capacity of 445 mAh/g at a high current

72 density of 2 A g^{-1}.[12] An exciting research by Park *et al*. explored coaxial carbon

73 nanofiber/NiO core-shell nano cables with an outstanding reversible capacity of 825 mAh g^{-1}

74 at a current density of 0.2 A g^{-1}.[13] Further, Shao and co-authors developed a freestanding

75 NiO/Graphene form anode composite, which exhibited a capacity of 640 mAh g^{-1} after 50

76 cycles at 100 mA g^{-1} and an excellent rate capability of 330 mAh g^{-1} at a current density of

77 1 A g^{-1}.The authors claimed that the outstanding electrochemical performance of the composite

78 is a result of the synergistic effect between the NiO and graphene form (GF) components. The

79 graphene form not only enhance the electrical conductivity but also act as a flexible substrate

80 for NiO and prevent the diffusion of NiO particles into the electrolyte during cycling.

81 Moreover, the unique hierarchical hollow structure of NiO effectively reduces the electrode

82 stress by controlling the volume change.[22]

83   Despite many efforts in the design of NiO/ carbonaceous composites, several challenges

84 remain in developing an ideal composite to solve issues such as conductivity and synthesis

85 procedures. For example, the graphene/NiO composites synthesis processes require several

86 steps, raising questions about the scalability and practicality of the materials. Another issue

87 described in the literature is decoupling the composite components during the cycling process

88 of Li-ion with graphene and NiO. The oxide nanoparticles tend to aggregate into clusters with

89 high local impedance after a few cycles, leading to a substantial decline in capacity.

90   In this work, we introduce a nanocomposite anode of NiO on a 3D carbon network

91 produced by expanding graphite into nanoflowers (NiO-GNF). The synergy between NiO and

92 the conductive carbon platform significantly improved the anode performance in Li-ion

93 batteries. Firstly, the 3D carbon nanoflower backbone provided a large surface area and

4

94 excellent conductivity to the active materials. Secondly, the NiO partially intercalated into the

95 graphite gallery, expanding the interlayer lattice distance and promoting faster Li^+ transport

96 and larger storage capacity. Thirdly, the well-designed nanoflower structure buffered the

97 volumetric changes during the charge and discharge, significantly improving the cycle life,

98 which was investigated in detail.

RESULTS AND DISCUSSION

99

100

101 A schematic illustration of the proposed mechanism for the NiO-GNF is displayed in Figure

102 1a. This work used nickel salt and bulk graphite powders as raw materials to derive nickel-

103 encapsulated expanded graphite. In the first step, during the hydrothermal reaction, nickel,

104 sodium, and citrate ions intercalate into the bulk graphite matrix to derive an intercalated

105 graphite compound (GIC). Next, the gaseous substances trapped between the graphitic layers

106 are released progressively, due to which the interlayer spacing between the sheets increases.

107 The vigorous hydrothermal conditions and continuous *in-situ* gas formation further weaken the

108 Van der Waals forces, resulting in exfoliated graphitic nanosheet formation. Simultaneously,

109 the nickel ions in the hydrothermal chamber nucleate and grow to form Ni nanostructures

110 within the graphite sheets resulting in Ni intercalated expanded graphitic nanostructures.

111 Moreover, the formation of expanded graphite particles effectively prevents the aggregation of

112 Ni nanostructures due to steric hindrance. The formed composite indicates nest-like structures

113 after synthesis (**Figure S1**). However, the morphology transformed into peony-like 3D

114 structures following heat treatment, which might be due to the conversion of hydroxide to

115 oxides and the removal of various gases during the process.

116   X-ray diffraction (XRD), exhibited in **Figure S2,** and resembles NiO. The diffraction

117 peaks located at 2-Theta 37.2º, 43.3º, and 62.8º corresponds to (111), (200), and (220) planes

of cubic NiO, respectively (JCPDS 73-1523). [23] The inter-planer spacing (d-spacing) of 0.24 nm was observed for the peak at 43.3°. In addition, the NiO-GNF nanocomposite (**Figure S3**) displayed additional peaks at 26.4° and 54.23° attributed to the graphitic backbone (JCPDS 01-0640).[24] Raman spectroscopic analysis also confirms the presence of the NiO phase in the NiO-GNF composite. As seen in **Figure S4,** two significant peaks can be observed for the petal of a peony-like structure, a prominent peak at ~ 500 cm^{-1} and a broad peak at around 1062 cm^{-1} corresponding to NiO first (1P) and second-order phonon (2P) scattering respectively.[25]

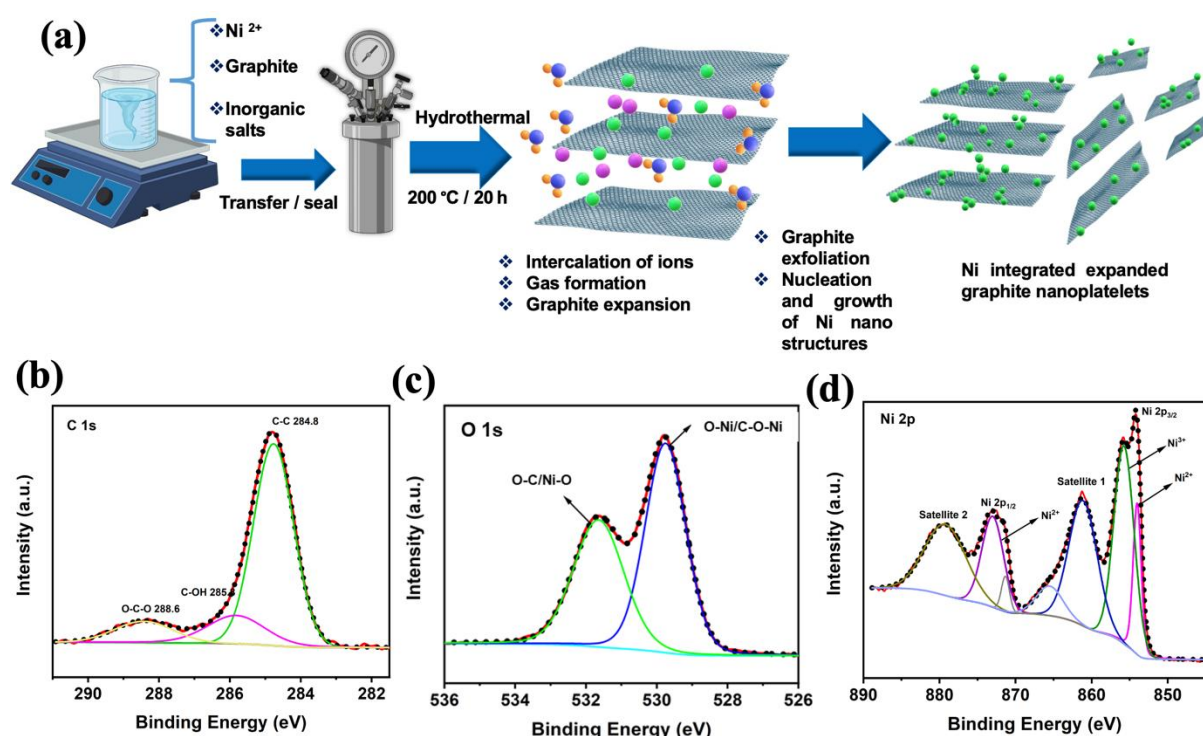

Figure 1. Synthesis and characterization of NiO/GNF. (a) Schematic illustration of peony-like 3D architecture formation using nickel salt and bulk graphite powders as raw materials to derive nickel-encapsulated expanded graphite. During the hydrothermal reaction, nickel, sodium, and citrate ions intercalate into the bulk graphite matrix to derive an intercalated graphite compound. The hydrothermal treatment and continuous *in-situ* gas formation weaken the Van der Waals forces, resulting in Ni-integrated expanded graphite nanoplatelets.

Deconvoluted XPS spectra of (b) C 1s, (c) O 1s, and (d) Ni 2p confirm the chemical valence states of the NiO/GNF composite.

X-ray photoelectron spectroscopy (XPS) was carried out to confirm the chemical valence states of the NiO/GNF composite and to understand their elemental compositions (**Figure 1b-d**). XPS survey spectrum shown in **Figure S5** verifies the presence of carbon (C), nickel (Ni), and oxygen (O). **Figure 1b** displays the C1s spectrum with binding energy at 284.8 eV corresponding to sp^2-hybridized carbon (C–C bond). Additionally, two low-intensity peaks can be detected at ~285 and 288 eV, corresponding to the sp^3 hybridized C–OH and O-C-O bonds.[26] The O1s spectrum exhibits two significant peaks at 529.4 and 531.7 eV, which can be ascribed to the metal-oxygen bonds such as O-Ni /C–O–Ni and the O-C/Ni-O respectively (**Figure 1c**). The results of the C1s and O1s peaks suggested the link between NiO and the graphitic backbone goes beyond the simple physical or chemical adsorption due to strong chemical bonds.[27, 28] The Ni2p spectrum experiences two-edge splits due to spin-orbital coupling (**Figure 1d**). The binding peaks observed at ~854 and ~872 eV and their satellite peaks at ~862 and ~879 can be attributed to the respective $2p_{3/2}$ and Ni $2p_{1/2}$ spin-orbit levels of NiO. Additional shoulder peak at ~ 855 eV might be due to surface oxidation of NiO to Ni_2O_3.
149

Figure 2. SEM images: (a and b) bulk NiO/graphite powders before hydrothermal treatment showing bulk particles and flakes, (c-f) corresponds to samples derived after hydrothermal process where (c) displays crumpled thin nano-sheet, and (d-f) higher magnification NiO-GNF composite material displaying an interconnected petal morphology with uniform distribution of exfoliated EG sheets encapsulated with NiO.

Figure 2 shows scanning electron microscope (SEM) images of the bulk NiO/graphite powders before and after hydrothermal and calcination steps. The hydrothermal process significantly altered the surface morphologies displaying the crumpled thin nano-sheet morphology of expanded graphite **(Figure 2c)**. Similarly, NiO-GNF composite experiences highly porous peonies-like reticulation, as illustrated in **Figure 2 d-f**. A detailed look through higher magnification SEM (**Figure 2e&f**) reveals an interconnected petal morphology with uniform distribution of exfoliated EG sheets over the petals. This observation indicates the simultaneous occurrence of Ni nanostructures nucleation and the slow release of gaseous substances during the hydrothermal process transforming the bulk powders into highly ordered

NiO-encapsulated GNF structures. The presence of carbon, Ni, and O was re-validated through SEM/EDX mapping **(Figure S6).** Furthermore, the NiO percentage in the NiO-GNF composite was calculated as 61.98 wt. %. (See TGA interpretation, **Figure S8**). Compared with pristine NiO, NiO-GNF composite could lead to uniform conductivity, thereby modulating NiO's electrical resistance behavior during the Li-ion battery electrochemical performance.

Figure 3. TEM image of derived samples (a) exfoliated graphene sheets; (b) displays the presence of scattered NiO nanoparticles (c) displays *d-spacing* values taken at three different regions (marked i, ii, and iii) correspond to differences in interlayer spacings at various spots where (d) show 0.33 nm, (e) 0.36 nm and (f) 0.37 nm. TEM-EDS mapping area is shown in

174   (g), and (h) shows the presence of all expected elements where (i) corresponds to carbon, (j)

175   oxygen, and (k) nickel.

176   Transmission electron microscopy (TEM) (**Figure 3a-k)** was carried out to understand

177   the peeling of bulk graphite into thin expanded graphite nanoplatelets during the hydrothermal

178   process. **Figure 3a** displays the stacking of multilayer expanded graphite sheets, and **figure 3b**

179   shows the presence of scattered NiO particles with white patch-like morphology. To confirm

180   the expanded graphite formation, we measured *d-spacing* at three different regions (**Figure 3c**

181   **inset**) and identified the following values: (i) 0.33, (ii) 0.36, and (iii) 0.37 nm. These reflections

182   are typical of morphed graphene corresponding to (110) planes which agrees with the XRD

183   peak observed ~26° (2θ). The increase in the interlayer spacing could be attributed to layer

184   expansion during the hydrothermal treatment and the subsequent calcination step. Similarly,

185   the high-resolution transmission electron microscopy (HRTEM) image of NiO particles

186   (Figure S7) displays lattice fringes with interplanar spacing of 0.26 nm and 0.2 nm,

187   corresponding to (111) and (200) crystal planes, respectively. [29] The NiO-GNF samples were

188   further characterized through TEM-EDS mapping to confirm the presence of different

189   elements, and the results are shown in (**Figure 3g-k**). As seen, the TEM-EDS results display

190   uniform distribution of C, Ni, and O elements, confirming the possibility of transforming bulk

191   graphitic structures to few-layered graphene sheets encapsulated with NiO.

192   It is well-known that surface area and pore hierarchy of material plays a significant role

193   in the Li-ion transport phenomenon. Therefore, we carried out nitrogen adsorption-desorption

194   analysis to measure the changes in surface area and pore size distribution of NiO-GNF

195   composite and pristine NiO. Both materials displayed typical type IV isotherm curves,

196   indicating the presence of mesoporous features. However, the NiO-GNF sample revealed

197   multistage pore size distribution showing the presence of micro, meso, and macro pores for

198   composites, while the NiO is predominantly microporous (< 2 nm). The micropores probably

199   arise due to the loss of several organic O and H species during the hydrothermal treatment,

200   while graphene sheets contribute to mesopore formations. The total pore volume, average pore

201   diameter, and specific surface area of NiO-GNF were 0.33 cm^3 g^{-1}, 7.29 nm, and 178 m^2 g^{-1},

202   respectively, and for the pristine sample, it was 0.13 cm^3g^{-1}, 6.06 nm, and 82.9 m^2 g^{-1}

203   respectively. **(Figure S9)**. The multistage size distribution and higher surface area of NiO-GNF

204   suggest enhanced Li-ion migration and comparatively higher Li-ion storage capacity, which is

205   favorable for fabricating high-capacitive energy storage material.
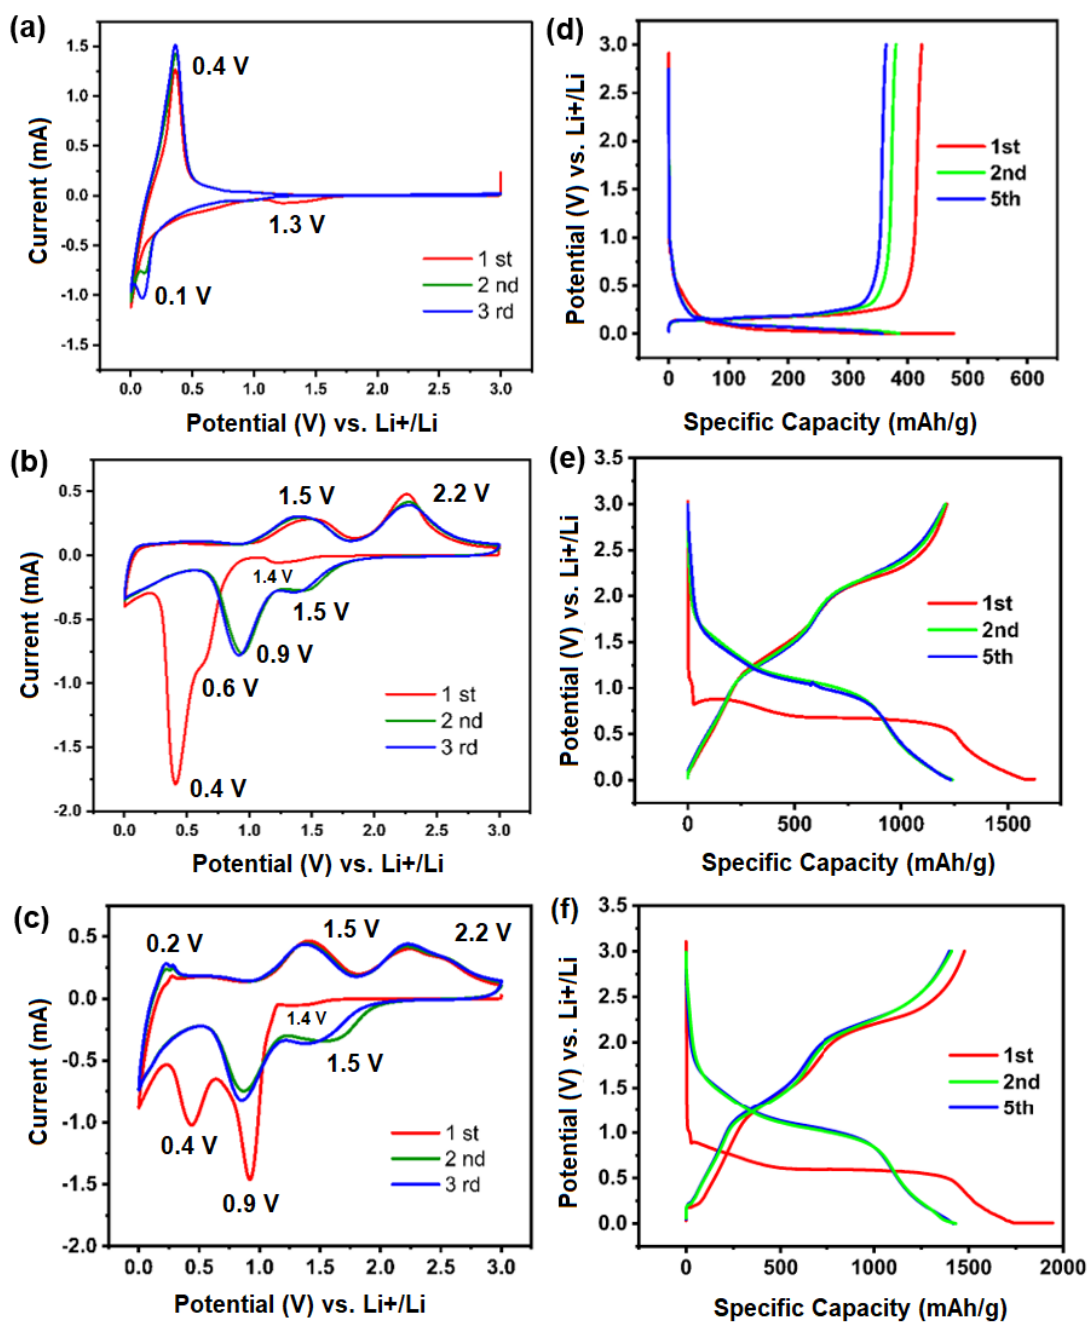

Figure 4. Cyclic voltammetry profiles: (a) EG, (b) NiO, and (c) NiO/GNF at a scan rate of 0.1 mV s^{-1} in the voltage range of 0.001–3.0 V. The discharge/charge profiles: (d) EG, (e) NiO, and (f) NiO/GNF in the 1st, 2nd, and 5th cycles in the potential range of 0.001–3.0 V at 0.1 A g^{-1}.

We tested the derived NiO-GNF as an anode in a two-electrode half-cell Lithium-ion battery where Li foil acts as the counter electrode, and, for comparison, we tested pristine

213 expanded graphite and NiO (**Figure 4**). The cyclic voltammetry (CV) measurements were

214 conducted at the potential window between 0.001– 3 V (vs. Li^+/Li)) at a very slow scan rate of

215 0.1 mV s^{-1}. **Figure 4a- c** shows the first three CV cycles of the EG, NiO, and NiO-GNF. In the

216 first cathodic scan (**Figure 4a**), EG displays a minor peak at ~1.3 V associated with the

217 reductive destruction of the electrolyte and subsequent formation of a solid electrolyte interface

218 (SEI).[30] The noticeable reduction at 0.1 V indicates the intercalation of lithium ions into a

219 multilayer graphene.[31] At around 0.4 V, a sharp peak of oxidation corresponding to the de-

220 intercalation of Li-ions from the LiC_x complex was observed.[31] In contrast, NiO and

221 NiO/GNF share a few CV peaks in common, signifying the dominant contribution of NiO

222 (**Figure 4b, c**). Both NiO and NiO-GNF exhibit a cathodic peak at 0.4 V vs. Li^+/Li,

223 corroborating the irreversible formation of SEI and the reduction of NiO.[32] However, the

224 peak is much stronger for pristine NiO compared to NiO-GNF, suggesting catalytic activity of

225 NiO in electrolyte decomposition and an additional SEI layer formation.[33] In addition to the

226 peak at 0.4 V, the first cathodic scans of NiO and NiO-GNF systems also show a reoccurring

227 two oxidation peaks at 0.6/ 0.9 V and 1.4 V, respectively. This suggests the presence of NiO

228 traces in both electrodes, which get reduced in the first cathodic scan.

229   The reduction process can be related to the conversation of NiO to metallic Ni and

230 nickel suboxides (NiO + 2Li$^+$ + 2e → Ni + Li$_2$O + Ni suboxides).[10, 11] In addition, we

231 noticed that the intensity of the peak at 0.9 V is much stronger and shifted in NiO-GNF

232 compared to pristine NiO supporting an increased lithiation capacity. The enhanced capacity

233 can be attributed to the intercalation of lithium with expanded graphitic sheets resulting in

234 improved electrical conductivity and fast electron transfer kinetics.[34] The cathodic peak seen

235 at 1.4 V in both systems has shifted towards a more positive potential of 1.5 V in subsequent

236 cycles, which probably relates to the formation of various Ni suboxides during the first

237 cycle.[10] The anodic oxidation peaks observed at 1.5 and 2.2 V in both NiO and NiO-GNF

238 systems can be related to the oxidation of Ni or Ni suboxides to NiO (Ni + Ni suboxides + Li_2O

239 $\rightarrow$ NiO + $2Li^+$ + 2e). Additionally, a reoccurring mild oxidation plateau was observed only in

240 the NiO/GNF system at 0.2 V, which might possibly be due to the de-intercalation of Li-ions

241 in graphitic strctures.[12]

242 **Figure 4d-f** displays the galvanostatic charge/discharge curves recorded at a current

243 density of 0.1 A g^{-1} after the 1st, 2nd, and 5th cycles. The EG samples display an initial discharge

244 capacity of 476.8 mAh g^{-1} and a charge capacity of 423.1 mAh g^{-1}, resulting in initial

245 Coulombic efficiency (ICE) of 88.7 %. The comparatively higher capacity of EG can be

246 attributed to the improved electrical conductivity of expanded graphite nanoplatelets and

247 enhanced ion storage due to enlarged interlayer spacing. Similarly, the initial discharge/charge

248 capacities for the pristine NiO were 1626 mAh g^{-1} and 1214 mAh g^{-1}, respectively, and the

249 ICE was 74.6 %. Compared to the NiO samples, NiO/GNF composite delivered a higher initial

250 discharge/charge capacity of 1945/1477 mAh g^{-1} and an enhanced ICE of 76 %.

251 However, the capacity of the following discharge cycles of three LIBs was lower than

252 that of the first cycle, which was associated with the SEI irreversibility and some

253 undecomposed Li_2O phase, which agrees with the CV results. Furthermore, during the 5th

254 cycle, NiO achieved a discharge/charge capacity of 1236/1207 mAh g^{-1} with an excellent

255 Coulombic efficiency (CE) of 97.6 %. Similarly, the discharge/charge capacities of NiO-GNF

256 were 1437 mAh g^{-1} and 1415 mAh g^{-1}, respectively, resulting in superior CE of 98.5 % due to

257 the synergistic effect of NiO-GNF which was observed widely in previous studies.[10, 34] In

258 addition, a significant capacitive contribution from expanded graphite can be expected due to

259 increased interlayer distance. The 2nd and 5th discharge curves of NiO and NiO/GNF

260 overlapped, suggesting more active material utilization over the cycling due to electrode

261 conditioning.

262   We then evaluated the rate capability of the NiO-GNF electrode and compared it with

263   EG and pristine NiO electrode, as shown in **Figure 5**. The NiO/GNF exhibits average

264   capacities of 1429,1287,1148,1008, 821, and 752 mAh g^{-1} at current densities of 0.1, 0.2, 0.5,

265   0.8, 1, and 1.2 A g^{-1}, respectively. The recorded capacities for the NiO-GNF electrode at

266   different current densities were higher than those of EG and pristine NiO, revealing fast

267   electrode kinetics resulting from the synergistic effect of NiO and graphitic nanomaterials

268   (**Table S1**).[10, 34] When cycling at a current density of 0.1 A g^{-1}, the NiO-GNF electrode

269   almost recovered its initial capacity, indicating excellent rate capability. In comparison, the

270   NiO electrode recovered ~91.2 %, signifying the GNF backbone's role in enhancing the

271   electrode's electrical conductivity and integrity. Further, the resultant capacity of 752 mAh g^{-1}

272   at an ultra-high current density of 1.2 A g^{-1} was slightly higher than the theoretical capacity of

273   NiO (i.e.,) 718 mAh g^{-1}. This further explains the NiO-GNF composite's excellent rate

274   capability in the present work, which was significantly improved to the reported results such

275   as NiO/RGO (564.5 mAh g^{-1}/ 0.8 A g^{-1})[10]; NiO/3D graphene (445 mAh g^{-1}/ 2 A g^{-1})[35];

276   NiO/graphene (~ 250 mAh g^{-1}, 1.5 A g^{-1})[25]; NiO/graphene NS (657 mAh g^{-1}, 1.436 A g^{-1}

277)[36]; NiO /graphene form (210 mAh g^{-1}, 2 A g^{-1})[22] and graphene@NiO@ carbon (580

278   mAh g^{-1},1.6 A g^{-1})[37].
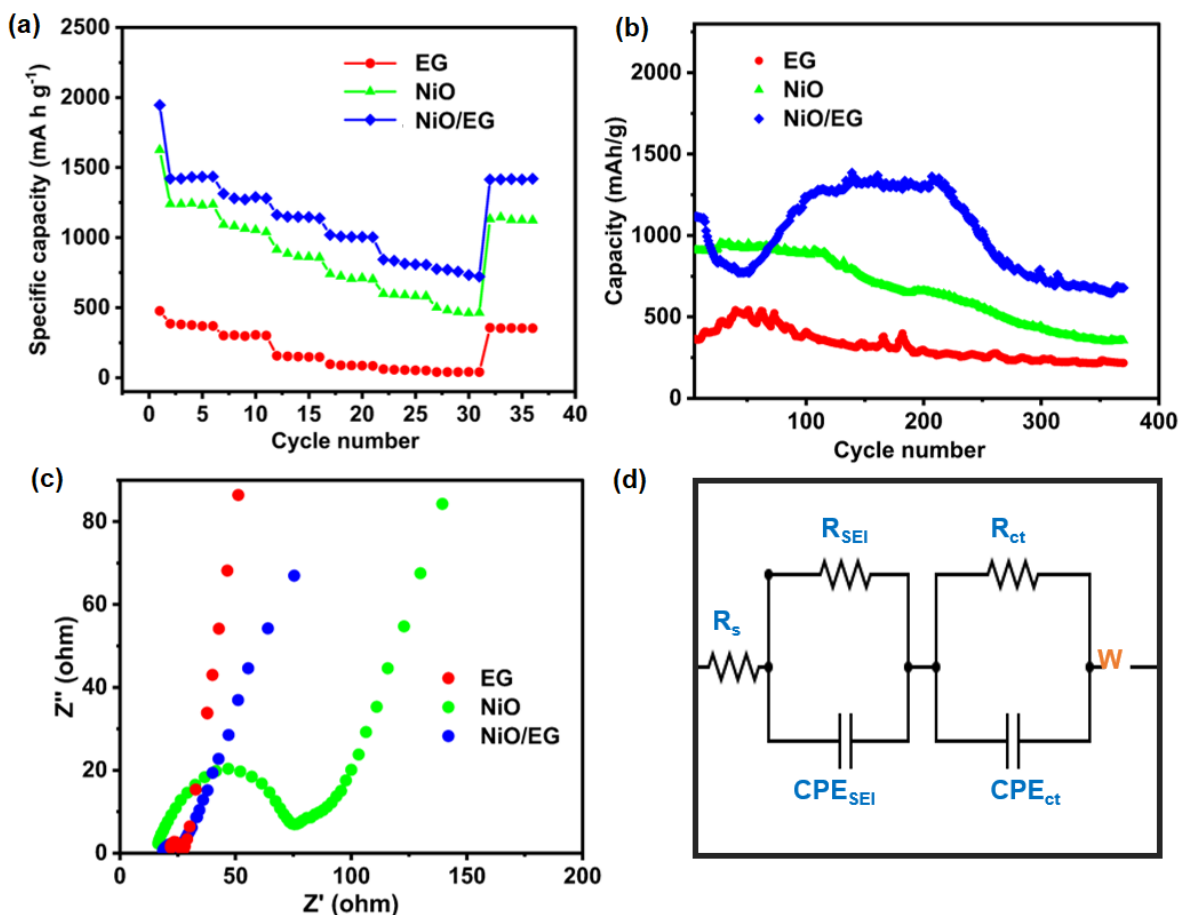

279

280

281

282

Figure 5. Lithium-ion battery performance of EG, NiO, and NiO-GNF. (a) Rate capability at different current densities, (b) Long-term cycling at 0.5 A g^{-1} in the potential range of 0.001–3.0 V, (c) The electrochemical impedance spectroscopy after the 5th cycle in the frequency range from 100 kHz to 0.01 Hz, and (d) The equivalent circuit of the cells used to simulate EIS curves.

We then evaluated the cyclic stability of the NiO/GNF electrode, which exhibited significantly higher stability than pristine NiO (See **Figure 5b**). The composite electrode delivered a capacity of 678.2 mAh g^{-1} after 370 cycles at 0.5 A g^{-1}, corresponding to 60.7 % retention of its 6th cycle capacity. In comparison, the EG provided a capacity of 86.6 mAh g^{-1} after 370 cycles, whereas the pristine NiO experienced rapid capacity fade and delivered a capacity of 354 mAh g^{-1}. It is worth noting that the NiO-GNF electrode displayed four distinct stages in its cycling performance: initial capacity fading, a trend of increasing capacity from

16

296 approximately 50 to 100 cycles, capacity stabilization from around 100 to 220 cycles, and

297 ultimately capacity fading until 370 cycles. Previous studies have observed the same cycling

298 performance pattern for nickel oxides and their graphitic carbon composites over long term

299 cycling.[38-41] The very first capacity decreasing trend could be attributed to the continuous

300 formation of a solid-electrolyte interphase (SEI) layer on the anode surface and loss of Li ions

301 as a result of anode activation. The second capacity increasing trend attributable to the

302 enhanced Li- ions diffusion into the interior confines of the NiO-GNF composites, resulting in

303 the exposure of new active sites for lithium-ion storage. The third period of capacity

304 stabilization suggests the formation of a stable solid-electrolyte interphase (SEI) layer and that

305 all available interior active sites have been successfully accessed, presenting a reversible Li-

306 ion storage. The final capacity loss could be explained from following reasons: degradation

307 and reformation of SEI layer, particle fractures and loss of anode active materials due to

308 mechanical stress from continuous Li-ion insertion and extraction processes, Li dendrites

309 formation, electrolyte decomposition and impedance growth.[42]

310   Additional explanations for these observations were drawn through electrochemical

311 impedance spectroscopy (EIS). **Figure 5d** explains the equivalent circuit used to simulate the

312 EIS results. The high-frequency intercept (R_s) symbolizes the electrolyte's ohmic resistance

313 arising due to surface film formation. Correspondingly, the diameter of the semi-circle refers

314 to the R_{SEI}, the resistance due to the SEI layer, and R_{ct}, the charge-transfer resistance generates

315 towards Li-ion at the electrode/electrolyte interface.[11] The depressed semicircles signify the

316 presence of inhomogeneous surfaces; hence a constant phase element (CPE) is used in the

317 equivalent circuit instead of a pure capacitance. Therefore, CPE_{SEI} and CPE_{ct} represent the SEI

318 and double layer capacitance, respectively, and Warburg impedance W was attributed to Li-

319 ion diffusion.[43, 44] The R_{ct} for NiO-GNF electrodes was very low as 0.636 Ω. In contrast,

320 the resistance of NiO was considerably higher at 44.7 Ω **(Figure 5c)**. These observations

321 clearly demonstrate that NiO/GNF composite generates faster and better electrochemical

322 kinetics with successful EG integration. Furthermore, the smaller semi-circle in NiO-GNF

323 confirms the control pulverization of NiO and subsequent inhibition of additional SEI layer

324 growth, validating the cyclic voltammetry results. In general, the electrochemical performances

325 we have observed are encouraging when compared to recent findings on the application of

326 NiO/carbon composites as anode material for Li-ion batteries **(Table S2).**

327

328

329 **CONCLUSION**

330

331 In summary, we explored a one-step hydrothermal synthesis approach for fabricating NiO-

332 GNF composite material. During the hydrothermal process, the bulk graphitic particles

333 transformed into expanded graphite nanosheets encapsulating the NiO nanoparticles within

334 their carbon network. The chemical environment and surface morphology of the derived NiO-

335 GNF composite materials was confirmed using several analytical techniques. Notably, the

336 integration of expanded graphite with NiO nanostructures demonstrated significantly improved

337 electrochemical performance, improved electrode integrity, enhanced Li-ion storage, and

338 buffered electrode stress. The synergistic interaction between the expanded graphite and the

339 NiO resulted in a 22.4 % capacity retention enhancement and a 324 mAh g^{-1} capacity

340 improvement compared to the pristine NiO in the LIB application. To the best of our

341 knowledge, the observed electrochemical performance of NiO-GNF, which was ~678.2 mAh

342 g^{-1} at 0.5 A g^{-1} over 370 cycles, is a significant improvement compared to the reported carbon-

343 based NiO composites. Overall, the derived material can be considered an excellent electrode

344 due to its ease of synthesis, scalability, enhanced capacity retention, and long-term cyclability.

18

EXPERIMENTAL SECTION

Synthesis of NiO/GNF nanocomposite

Nickel sulfate hexahydrate, sodium acetate trihydrate, and trisodium citrate were purchased from Sigma Aldrich, UK. The natural flake graphite powder (100 mg, <1 mm) was dispersed in a 40 mL aqueous solution containing 0.2 mol dm^{-3} nickel sulfate hexahydrate,1 mol dm^{-3} sodium acetate trihydrate and 0.5 mol dm^{-3} trisodium citrate. The mixture was then transferred into a Teflon-lined stainless autoclave and heated at 200 °C for 20 h. The residue was thoroughly washed with de-ionized water and collected through vacuum filtration. Finally, the samples were heat treated at 350 ℃ for 12 h to convert hydrothermal intermediate hydroxide product into NiO. For comparison, NiO and EG were synthesized through the same approach.

Material characterization

The crystal structure of the samples was evaluated using a Rigaku D/Max Ultima II powder XRD with Cu Kα ($\lambda = 0.154$ nm) irradiation in the 2θ range of 20° to 80° at a scan rate of 0.02°. The surface morphology and elemental scans of the synthesized materials were evaluated using High-resolution field-emission scanning electron microscopy FEI Quanta 400F ESEM FEG operated at 20 kV, which was fitted with energy-dispersive X-ray spectroscopy (SEM-EDS). Raman measurements were carried out using a JY Horiba Lab RAM HR. A laser power of 28 μW was used as an excitation wavelength of 514 nm. All samples were gold-coated (~7nm) before analysis. The increase in interlayer spacing and EG formation was observed using a high-resolution transmission electron microscope (HRTEM, JEOL JEM-2100F, functioning at 200 kV) facilitated with EDX. X-ray photoelectron spectroscopy was employed to evaluate the chemical composition of the material. XPS analysis was carried out using a PHI Quantera X-ray photoelectron spectrometer with a chamber pressure of $5 \times 10{-}9$ Torr, and an Al cathode

370 was used as the X-ray source. The pass energies were set to 26.00 eV for the core-level scan,

371 and the source power was set at 100 W. Thermogravimetric analysis (TGA) was performed on

372 a TA Instrument- SDTQ600 under air with a heating rate of 10 °C min^{-1}. The

373 Brunauer−Emmett−Teller (BET) technique calculated the materials' specific surface area and

374 pore size distributions. The materials were evaluated using nitrogen sorption under 77.4 K by

375 Autosorb iQ station 1 system. All samples were degassed at 200 °C for 12 h before the analysis.

376

377 **Electrochemical measurements**

378 The NiO-GNF composite's electrochemical performance was assessed using a 2032-type coin

379 cell for lithium-ion batteries. In addition, a comparitive electrochemical analysis was

380 performed for the NiO and EG separately. The slurry was prepared by mixing active material

381 (70 wt. %), Super P (20 wt. %), and sodium carboxymethyl cellulose binder (10 wt. %, CMC,

382 Sigma-Aldrich, 99%) and pasted on the copper current collector through the doctor blade

383 technique. The electrodes were dried at 120 °C overnight in a vacuum oven (OV-11, Jeio Tech

384 Co.) and punched into electrodes (d=13 mm) with an active materials mass loading over the

385 electrodes ranging from 2 to 3 mg cm^{-2}. The LIB half cells were fabricated using a lithium foil

386 (MTI Corp.) as a counter electrode, a glass microfiber filter (GF/B, pore size- 1.0 μm,

387 Whatman) as a separator, and 1M Lithium hexafluorophosphate (LiPF$_6$) in ethylene carbonate:

388 diethyl carbonate (1:1 vol.%) containing 2 % vinylene carbonate and 3% fluoroethylene

389 carbonate (Solvionic, battery grade) as the electrolyte. The coin cells were assembled in a dry

390 glove box under an argon atmosphere (Lab star eco, MBRAUN) with moisture and oxygen

391 concentration below 1ppm. The cyclic voltammetry (CV) examinations of as-built coin cells

392 were evaluated on an electrochemical workstation (Iviumstat, Ivium Technologies) within the

393 potential range of 3.0 to 0.001 V (versus Li/Li$^+$) at a scan rate of 0.1 mV s^{-1}. Galvanostatic

394 charge-discharge profiles and cycling performance were evaluated in the potential range of 3.0

to 0.001 V (vs. Li/Li+) at various current densities (Neware battery tester, BTS 4000). Electrochemical impedance spectroscopy (EIS) was measured over a frequency range of 0.01 Hz – 100 kHz with an amplitude of 5 mV.
